Abstract

Since McCabe’s cyclometric measure, structural complexity have been playing an important role measuring the complexity of programs. Complexity metrics are used to achieve more maintainable code with the least bugs possible.

C++ Standard Template Library (STL) is the most popular library based on the generic programming paradigm. This paradigm allows implementation of algorithms and containers in an abstract way to ensure the configurability and collaboration of the abstract components. STL is widely used in industrial softwares because STL’s appropriate application decreases the complexity of the code significantly.

Many new potential errors arise by the usage of the generic programming paradigm, including invalid iterators, notation of functors, etc.

In this paper we present many complexity inconsistencies in the application of STL that a precise metric must take into account, but the existing measures ignore the characteristics of STL.

Keywords: metrics, generic programming

1. Introduction

1.1. Software complexity metrics

Metrics play an important role in modern software engineering. Testing, bugfixing cover an increasing percentage of the software lifecycle [13]. In software design
the most significant part of the cost is spent on the maintenance of the product. The cost of software maintenance highly correlates with the structural complexity of the code. The critical parts of the software can be identified in the early stages of the development process with the aid of a good complexity-measurement tool.

In the software development process abstractions play a central role. An abstraction focuses on the essence of a problem and excludes the special details. Abstractions depend on many factors: user requirements, technical environment, and the key design decisions. In software technology a paradigm represents the directives in creating abstractions. The paradigm is the principle by which a problem can be comprehended and decomposed into manageable components. In practice, a paradigm directs us in identifying the elements in which a problem will be decomposed and projected. The paradigm sets up the rules and properties, but also offers tools for developing applications. These methods and tools are not independent of their environment in which they occur.

The last 50 years of software design has seen several programming paradigms from automated programming and the FORTRAN language in the mid-fifties, to procedural programming with structured imperative languages (ALGOL, Pascal), to the object-oriented paradigm with languages like Smalltalk, C++ and Java. However, it is important to understand that new paradigms cannot entirely replace the previous ones, but rather form a new structural layer on the top of them. Object-orientation is a new form of expressing relations between data and functions, however, these relations implicitly existed in the procedural paradigm.

Software metrics have always been strongly related to the paradigm used in the respective period. Metrics applied to different paradigms than the one they were designed for, might report false results [10]. The McCabe Cyclomatic complexity number [4] was designed for measuring the testing efforts of non-structural FORTRAN programs. Piwowarski [7], Howatt and Baker [3] extended the cyclomatic complexity with the notion of nesting level in order to describe structured programs better. After the object-oriented paradigm became widely accepted and used, both the academic world, and the IT industry focused on metrics based on special object-oriented features, like number of classes, depth of inheritance tree, number of children classes, etc. [2]. Several implementations of such metrics are available for the most popular languages (like Java, C#, C++) and platforms (like Eclipse).

1.2. **C++ Standard Template Library(STL)**

The C++ Standard Template Library (STL) is the most popular library based on the generic programming paradigm [1]. STL is widely-used, because the library is the part of the C++ Standard [12]. It consists of many useful generic data structures and generic algorithms, that work together with containers. STL is based on generalization and generalization results in simplified interface.

C++ STL consists of three main parts: containers, iterators and algorithms. Containers (e.g. vector, list, map, set, etc.) are the generalization of arrays, so they hold elements. Iterators guarantee access to the elements in containers. It-
erators are nested types of containers. Iterators are a generalization of pointers, their standard interface originates from pointer-arithmetic. Algorithms are fairly irrespective of the used container, because they work with iterators. For instance, we can use the \texttt{for\_each} algorithm with all containers. The complexity of the library is greatly reduced because of this layout. As a result of this layout we can extend the library with new containers and algorithms simultaneously. This is a very important feature, because object-oriented libraries do not support this kind of extension. The C++ standard guarantees the complexity of the operations.

STL applies the generic programming paradigm, so we can expect that the common metrics can fail on this library because of the metrics’ paradigm-dependence. As we will see, the old metric tools are not precise enough.

2. Positive effects

STL is a popular library, because it greatly reduces the complexity of a program from the view of programmers. The library offers many positive effects to code, but some of these effects cannot be measured by widely-used metrics.

STL makes the code more abstract, more powerful, more expressive, so programmers can avoid many mistakes [5]. STL is a standard library, many books and online references can be found (for example [1, 5, 12]).

3. Trivial inconsistencies

Many inconsistencies can be found between the common metrics and STL. Some of these inconsistencies are quite clear.

One of the most obvious inconsistency is the widely-used object oriented metrics fail on C++ Standard Template Library, because this library is based on generic programming and implementing classes is unnecessary. Of course, we use objects and classes when the STL is applied, but we can write STL-based code without any new classes. Hence, the object-oriented metrics may fail on STL-based programs.

Another important feature is that STL is standardized library, so names of functions and classes in the library are well-known. The names express their behaviour, for instance the \texttt{copy} algorithm copies elements, the \texttt{sort} algorithm sorts a container, etc. No external library can achieve this important feature, and no existing metric can measure this special advantage.

STL has been designed as a generic programming library, so STL has a reduced interface: algorithms can be applied to more container types. The basic usage of the library is easy of attainment because of the reduced interface. This is a good feature, because beginner programmers do not shy away from STL. But this point is also not measured.
4. Complexity inconsistencies

In this section we examine some more sophisticated problems.

4.1. Error diagnostics

Error diagnostics usually do not matter when measuring software complexity. Metrics ignore syntactical and semantical errors in the code and usually examine programs as error-free software.

A simple mistake in STL-based code causes very long and incomprehensible error diagnostics. For example, more thousand character long error messages are not rare and often refer to unknown and unseen types and objects. Sometimes the error message points to the implementation of STL.

Some software tools help us to reduce the complexity of the messages, but these tools depend on the compiler and STL implementation.

Modification or maintain of STL-based code can be more difficult because of the complicate error diagnostics, so we should take it into account.

4.2. Functors

C++ functors are special objects that offer an \texttt{operator()} to simulate function-calls. Functors are quite common objects in STL-based code, because functors can avoid the overhead of non-inline function calls and some problems about the name of template functions to get the code to compile.

The problems of functors are their special requirements. Functor classes are often inherited from special classes that only support some typedefs. The names of these base classes are \texttt{unary\_function} and \texttt{binary\_function}. These base classes do not increase the complexity of a functor from the viewpoint of STL programmer.

Functors are always passed by value. Polymorphism and value passing an object do not work together, because the object would be sliced. So, polymorphic functors are not allowed.

4.3. Sorted ranges

Many problem arise from the inadequate usage of sorted ranges. Some algorithms have a special precondition, e.g. the input range must be sorted (for example, \texttt{binary\_search}, \texttt{equal\_range}, \texttt{set\_union}, etc.). But the compilers do knot know what “sorted range” means, so the compiler cannot help us at this point. If we call an algorithm of this kind to an unsorted range, it causes undefined behavior. Unfortunately STLlint [14] cannot discover the improper usage of these algorithms. Using this kind of algorithms increases the complexity of the code.

Using the same sorting predicate to the sort and algorithm is important. If anyone violates this constraint it also leads to undefined behavior.
4.4. Dataflow

Dataflow models measure by the parameter-passing [11]. This means the complexity of a program is based on parameters: how to read or write the arguments.

A basic problem is that we cannot read all parameterflows from an STL-based code. For example we write a functor and we call an algorithm with this functor as an argument. It is invisible that the code will execute the functor’s functioncall operator.

Another problem is that we cannot decide if an algorithm modifies the container. For instance, let us consider the following two declarations. The find algorithm does not modify the container, but the sort algorithm does:

```cpp
template <typename InputIter, typename T>
InputIter find(InputIter first, InputIter last, const T& t);

template <typename RanIter>
void sort(RanIter first, RanIter last);
```

On the other hand, the parameters are not independent. A container is passed by two iterators that define the range. If we call an algorithm usually call it with special iterators: begin and end iterators. It is so common that the programmers cannot make a mistake. So, iterators as parameters are very closely to count them twice.

5. Some proposals

In the papers [9, 11] a multiparadigm metric is described. AV-graph measures three main points of a given program: the structure of the program, the dataflow in the program, and the complexity of the used data structures.

We have seen that the dataflow model is not precise enough. Informally speaking, the control structure also fails on STL-based code, because the usage of STL replaces many loops and if statements.

It is also a common problem what can we mean by complexity of the STL’s data structures. The complexity cannot be an STL implementation-specific value.

Complexity of STL’s data structures should be based on some “semantical concepts”: for instance, basic behaviour of the container (e.g. vector’s reallocating strategy), special parameters of a data structure, how copying works, etc.

6. Conclusion

C++ Standard Template Library is a widely-used library based on the generic programming paradigm. Software metrics are mostly paradigm-dependent, so we can expect that the common metrics fail on C++ STL. In this paper we present many inconsistencies between STL and the widely used metrics. Our aim is to calibrate an old metric to measure STL-based code.
References

The Standard Template Library (STL) is a software library for the C++ programming language that influenced many parts of the C++ Standard Library. It provides four components called algorithms, containers, functions, and iterators. The STL provides a set of common classes for C++, such as containers and associative arrays, that can be used with any built-in type and with any user-defined type that supports some elementary operations (such as copying and assignment). STL algorithms are independent of
